ON A CONVEX MEASURE OF DRAWDOWN RISK

LISA R. GOLDBERG[1] AND OLA MAHMOUD[2]

Abstract. Maximum drawdown, the largest cumulative loss from peak to trough, is one of the most widely used indicators of risk in the fund management industry, but one of the least developed in the context of measures of risk. We formalize drawdown risk as Conditional Expected Drawdown (CED), which is the tail mean of maximum drawdown distributions. We show that CED is a degree one positive homogenous risk measure, so that it can be linearly attributed to factors; and convex, so that it can be used in quantitative optimization. We provide an efficient linear program for minimum CED optimization and empirically explore the differences in risk attributions based on CED, Expected Shortfall (ES) and volatility. An important feature of CED is its sensitivity to serial correlation. In an empirical study that fits AR(1) models to US Equity and US Bonds, we find substantially higher correlation between the autoregressive parameter and CED than with ES or with volatility.

Key terms: drawdown; Conditional Expected Drawdown; deviation measure; risk attribution; convex optimization; serial correlation

We are grateful to Robert Anderson for insightful comments on the material discussed in this article; to Alexei Chekhlov, Stan Uryasev, and Michael Zabarankin for their feedback on a previous draft of this work; to Vladislav Dubikovsky, Michael Hayes, and Márk Horváth for their contributions to an earlier version of this article; and to Carlo Acerbi and an anonymous referee for providing detailed comments on a previous draft.

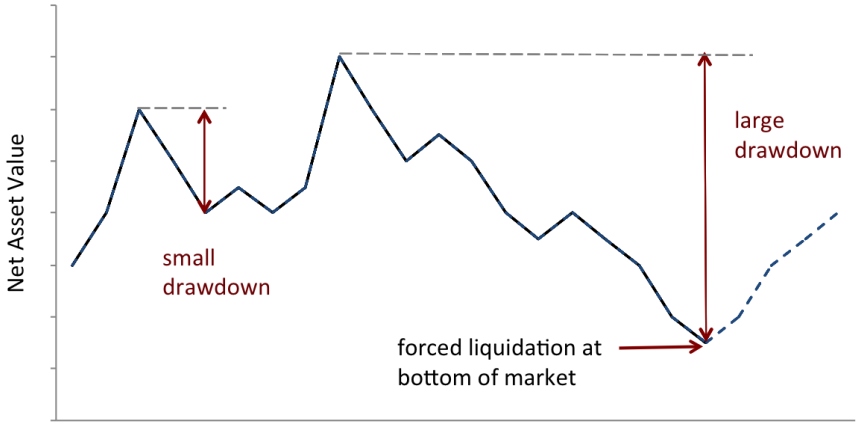

FIGURE 1.1. Simulation of a portfolio's net asset value over a finite path. A large drawdown may force liquidiation at the bottom of the market, and the proceeding market recovery is never experienced.

1. INTRODUCTION

A levered investor is liable to get caught in a liquidity trap: unable to secure funding after an abrupt market decline, he may be forced to sell valuable positions under unfavorable market conditions. This experience was commonplace during the 2007-2009 financial crisis and it has refocused the attention of both levered and unlevered investors on an important liquidity trap trigger, a drawdown, which is the maximum decline in portfolio value over a fixed horizon (see Figure 1.1).

In the event of a large drawdown, common risk diagnostics, such as volatility, Value-at-Risk, and Expected Shortfall, at the end of the intended investment horizon are less significant. Indeed, within the universe of hedge funds and commodity trading advisors (CTAs), one of the most widely quoted measures of risk is maximum drawdown. The notion of drawdown has been extensively studied in the literature of applied probability theory, which we review in Section 1.1. However, a generally accepted mathematical methodology for forming expectations about future potential maximum drawdowns does not seem to exist in the investment management industry. Drawdown in the context of measures of risk has failed to attract the same kind of applied research devoted to other more conventional risk measures.

Our purpose is to formulate a (i) mathematically sound and (ii) practically useful measure of drawdown risk. Our formalization of drawdown risk is achieved by modeling the uncertain payoff along a finite path as a time-ordered random vector $X_{T_n} = (X_{t_1}, \ldots, X_{t_n})$ representing return paths, to which a certain real-valued functional, the *Conditional Expected Drawdown*, is applied. Mathematically, the random variables X_{t_i} are transformed to the random variable $\boldsymbol{\mu}(X_{T_n})$, representing the maximum drawdown within a finite path. At confidence level $\alpha \in [0, 1]$, the *Conditional Expected Drawdown* CED_α is then defined to be the expected maximum drawdown given that some maximum drawdown threshold DT_α, the α-quantile of the maximum

drawdown distribution, is breached:

$$\mathrm{CED}_\alpha(\mathrm{X}_{\mathrm{T_n}}) = \mathbb{E}\left(\boldsymbol{\mu}(\mathrm{X}_{\mathrm{T_n}}) \mid \boldsymbol{\mu}(\mathrm{X}_{\mathrm{T_n}}) > \mathrm{DT}_\alpha\right).$$

In the context of risk measures, CED is convex with respect to portfolio weights, which means that it promotes diversification and can be used in an optimizer. It is also homogenous of degree one, so that it supports linear risk attribution under Euler's homogenous function theorem. Moreover, CED is a deviation measure in the sense of Rockafellar et al. (2002, 2006).

By focusing on the *maximum* of all drawdowns within a path of fixed length T, we address a highly relevant risk management concern affecting fund managers on a daily basis, who ask themselves: what is the expected maximum possible cumulative drop in net asset value within the investment horizon T? If this loss exceeds a certain threshold, the investor may be forced to liquidate. For a given investment horizon T, Conditional Expected Drawdown indicates this expected cumulative loss in excess of a threshold, and it can be measured for various confidence levels.

Because Conditional Expected Drawdown is defined as the tail mean of a distribution of maximum drawdowns, it is a downside risk metric perfectly analogous to Expected Shortfall, which is the tail mean of a return distribution. Hence, much of the theory and practice of Expected Shortfall carries over to Conditional Expected Drawdown.

We will show, however, that drawdown is inherently path dependent and accounts for serial correlation, whereas Expected Shortfall does not account for consecutive losses.

1.1. **Literature Review.** The analytical assessment of drawdown magnitudes has been broadly studied in the literature of applied probability theory. To our knowledge, the earliest mathematical analysis of the maximum drawdown of a Brownian motion appeared in Taylor (1975), and it was shortly afterwards generalized to time-homogenous diffusion processes by Lehoczky (1977). Douady et al. (2000) and Magdon-Ismail et al. (2004) derive an infinite series expansion for a standard Brownian motion and a Brownian motion with a drift, respectively. The discussion of drawdown magnitude was extended to studying the frequency rate of drawdown for a Brownian motion in Landriault et al. (2015). Drawdowns of spectrally negative Lévy processes were analyzed in Mijatovic and Pistorius (2012). The notion of drawup, which measures the maximum cumulative gain relative to a running minimum, has also been investigated probabilistically, particularly in terms of its relationship to drawdown; see for example Hadjiliadis and Vecer (2006), Pospisil et al. (2009), and Zhang and Hadjiliadis (2010).

Reduction of drawdown in active portfolio management has received considerable attention in mathematical finance research. Grossman and Zhou (1993) considered an asset allocation problem subject to drawdown constraints; Cvitanic and Karatzas (1995) extended the same optimization problem to the multi-variate framework; Chekhlov et al. (2003, 2005) developed a linear programming algorithm for a sample optimization of portfolio expected return subject to constraints on drawdown, which, in Krokhmal et al. (2003), was numerically compared to

shortfall optimzation with applications to hedge funds in mind; Carr et al. (2011) introduced a new European style drawdown insurance contract and derivative-based drawdown hedging strategies; and most recently Cherney and Obloj (2013), Sekine (2013), Zhang et al. (2013) and Zhang (2015) studied drawdown optimization and drawdown insurance under various stochastic modeling assumptions. Zabarankin et al. (2014) reformulated the necessary optimality conditions for a portfolio optimization problem with drawdown in the form of the Capital Asset Pricing Model (CAPM), which is used to derive a notion of drawdown beta. More measures of sensitivity to drawdown risk were introduced in terms of a class of drawdown Greeks in Pospisil and Vecer (2010).

In the context of quantitative risk measurement, Chekhlov et al. (2003, 2005) develop a qauantitative measure of drawdown risk called Conditional Drawdown at Risk (CDaR). Like CED, CDaR is a deviation measure (Rockafellar et al. (2002, 2006)). Unlike CED, however, CDaR focuses on all drawdowns rather than maximum drawdowns.

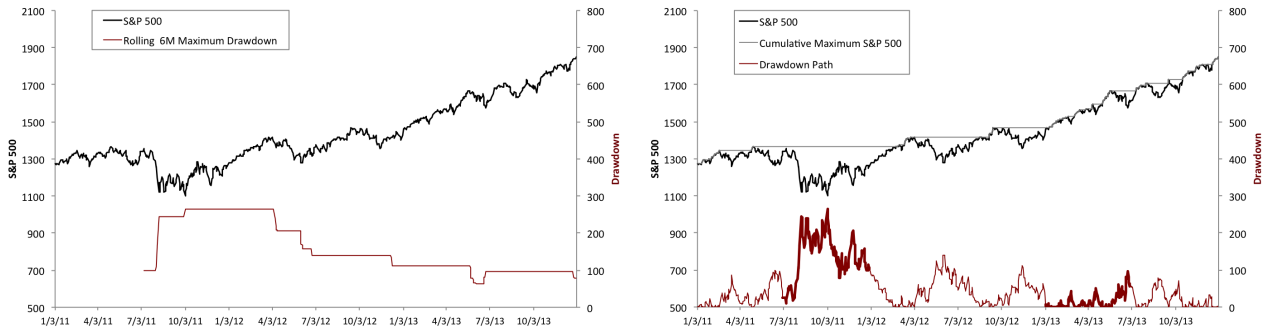
1.2. **Synopsis.** Drawdown risk is formalized in Section 2, which includes mathematical definitions of maximum drawdown and Conditional Expected Drawdown (CED). In Section 3, we axiomatize Conditional Expected Drawdown as a measure of risk. CED is shown to be positive homogenous and convex, but not *monetary* in the sense of Artzner et al. (1999). Moreover, we show that CED satsifies the axioms of deviation measures developed by Rockafellar et al. (2002, 2006). Section 4 illustrates how CED can be attributed to linear factors, since positive homogeneity ensures that the overall drawdown risk of a portfolio can be decomposed into additive subcomponents representing the individual factor contributions to drawdown risk. In Section 5, we provide a computationally efficient linear programming algorithm for a CED optimization problem. This enables investors to allocate funds in such a way that minimizes drawdown risk. Section 6 contains an empirical study analyzing drawdown risk and drawdown risk concentrations. We provide empirical support for a positive relationship between serial correlation and CED and further show that serial correlation in the assets manifests itself more in the drawdown risk concentrations than in those of Expected Shortfall or volatility. Concluding remarks and suggestions for further empirical research are given in Section 7.

2. Measuring Drawdown Risk

We work in a discrete-time universe, where there are two time parameters at play when we consider drawdown. The first is the length of the horizon — long horizons tend to yield larger drawdowns. The second is the granularity — more granular observations also tend to yield larger drawdowns.[1]

We represent cumulative portfolio returns by real-valued random variables $X\colon \Omega \to \mathbb{R}$ over a filtered probability space $(\Omega, \mathcal{F}, P)$. A time series of returns will be represented by a real-valued

[1]Consider the May 2011 flash crash. When working at a daily granularity, one never sees the flash crash drawdown, no matter how long the investment horizon. See Madhavan (2012) for an analysis of the flash crash.



(A) (B)

FIGURE 2.1. Daily prices of the S&P 500 from 1 January 2011 to 31 December 2013, together with (A) the backward-looking maximum drawdown within rolling six month periods (that is 125 business days) and (B) the corresponding daily rolling 6-month drawdown path.

discrete stochastic processes $(X_T) = \{X_t\}_{t\in T}$ (for T a totally ordered discrete set representing time). For simplicity, the time intervals between t_i and t_{i+1} are assumed to be equal for all $i \in \mathbb{N}$. For every finite ordered subset $T_n \subset T = \{t_1, \ldots, t_n\}$ of length n, we denote by X_{T_n} the random vector $(X_{t_1}, \ldots, X_{t_n})$ taking values in $\mathbb{R}^n$ and representing a finite path of the discrete process (X_T). At time t_j, the j-th element of the return path X_{T_n} is the simple return between t_1 and t_j, that is $X_{t_j} = P_{t_j}/P_{t_1} - 1$, where for all $i \leq n$, P_{t_i} denotes the price level (or net asset value) at time t_i.[2] Our main object of interest is the maximum drawdown along a path of realizations $(x_{t_1}, \ldots, x_{t_N})$ of the random vector X_{T_n} representing return paths. Formally, maximum drawdown will be defined via a random variable transformation, which is a vector-valued functional applied to the random vector X_{T_n}.

2.1. **Maximum Drawdown.** The maximum drawdown within a path is defined as the maximum absolute drop from peak to trough within that path. Formally, for a random vector $X_{T_n} = (X_{t_1}, \ldots, X_{t_n})$ representing return paths of length n, the maximum drawdown is the random variable defined by

$$\boldsymbol{\mu}(X_{T_n}) = \max_{1<i<j\leq n} \max\left\{X_{t_i} - X_{t_j}, 0\right\}.$$

Figure 2.1(A) shows the daily price series of the S&P 500 over the three-year period 2011–2013, together with the corresponding daily 6-month rolling maximum drawdown.

Remark 2.1 (Drawdown paths)**.** *An alternative way of looking at maximum drawdown is by first defining a* drawdown path. *Let $d : \mathbb{R}^n \to \mathbb{R}^n$ be the random variable transformation defined*

[2]Throughout this article, portfolios are assumed to be long-only. For long-short portfolios, the profit-and-loss may be more relevant than the return.

by $d(X_{T_n}) = (d_1(X_{T_n}), \ldots, d_n(X_{T_n}))$*, where for* $1 \leq j \leq n$*,* $d_j : \mathbb{R}^n \to \mathbb{R}$ *with* $d_j(X_{T_n})$ *given by*

$$d_j(X_{T_n}) = \max\left\{\max_{1\leq i\leq j}\{X_{t_i}\} - X_{t_j},\ 0\right\} \quad (1 \leq j \leq n).^3$$

The maximum drawdown within the path X_{T_n} *is then simply the largest amongst all drawdowns:*

$$\boldsymbol{\mu}\left(X_{T_n}\right) = \max\left\{d(X_{T_n}), 0\right\} = \max_{1\leq i\leq n}\left\{d_{t_i}, 0\right\}.$$

We make use of this alternative definition in some of the proofs later on in this article. Figure 2.1(B) shows the daily price series of the S&P 500 over a three-year period, together with the corresponding daily drawdown path over the same period.[4] *The highlighted sub-paths illustrate two different drawdown paths, each of a 6-month length. Note the difference in the magnitudes within the two drawdown paths. The larger (July to December 2011) occurred during a turbulent period; the smaller (January to June 2013) occurred in the midst of rising equity markets.*

2.2. **Maximum Drawdown Distributions.** Even though, in a given horizon, only a single maximum drawdown is realized along any given path, it is beneficial to consider the distribution from which the maximum drawdown is taken. By looking at the maximum drawdown distribution, one can form reasonable expectations about the size and frequency of maximum drawdowns for a given portfolio over a given investment horizon.

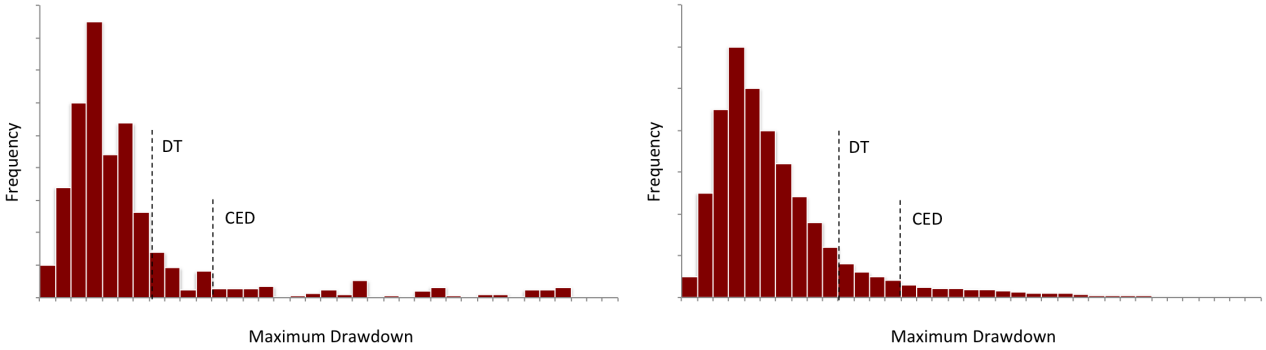
Figure 2.2 shows (A) the empirical maximum drawdown distribution (for paths of length 125 business days) of the daily S&P 500 time series over the period 1950 to 2013, and (B) the simulated distribution for an idealized Gaussian random variable. Both distributions are positively skewed, which implies that very large drawdowns occur less frequently than smaller ones.

Using Monte Carlo simlations, Burghardt et al. (2003) show that maximum drawdown distributions are highly sensitive to the length of the track record[5] (increases in the length of the track record shift the entire distribution to the right), mean return (for larger mean returns, the distribution is less skewed to the right, since large means tend to produce smaller maximum drawdowns, volatility of returns (higher volatility increases the likelihood of large drawdowns), and data frequency (a drawdown based on longer horizon data would ignore the flash crash).

The tail of the maximum drawdown distribution, from which the likelihood of a drawdown of a given magnitude can be distilled, is of particular interest in practice. Our drawdown risk metric, defined next, is a tail mean of the maximum drawdown distribution.

2.3. **Conditional Expected Drawdown.** Our proposed drawdown risk metric, the *Conditional Expected Drawdown* (Definition 2.3), measures the average of worst case maximum drawdowns exceeding a quantile of the maximum drawdown distribution. Hence, it is analogous to

[3]We suppress explicit reference to X_{T_n} if it is known from the context and will simply denote $d_j(X_{T_n})$ by d_{t_j}.
[4]Drawdowns are often quoted in terms of percentage cumulative loss rather than in absolute terms as depicted in Figure 2.1(B).
[5]The track record is understood as the length of the history of an investment fund since its inception.



(A) (B)

FIGURE 2.2. (A) Empirical distribution of the realized 6-month maximum drawdowns for the daily S&P 500 over the period 1 January 1950 to 31 December 2013, together with the 90% quantile (the *drawdown threshold* DT) and tail-mean (CED) of the distribution. (B) Distribution of 6-month maximum drawdowns for an idealized standard normally distributed random variable, together with the 90% quantile and tail-mean of the distribution.

the return-based Expected Shortfall (ES). Both ES and CED are given by the *tail mean* of an underlying distribution, namely that of the losses and maximum drawdowns, respectively.

Definition 2.2 (Tail mean (Acerbi and Tasche (2002b))). *For a confidence level* $\alpha \in (0,1)$*, the* lower α-quantile *of a random variable* X *is defined by* $q_\alpha(X) = \inf\{x \in \mathbb{R} \colon P(X \leq x) \geq \alpha\}$*. Assuming* $\mathbb{E}[X] < \infty$*, the* α-tail mean *of* X *is given by:*

$$\mathrm{TM}_\alpha(X) = \frac{1}{1-\alpha}\int_\alpha^1 q_\theta(X)d\theta,$$

which, for continuous distributions, is equivalent to the tail conditional expectation given by $\mathrm{TM}_\alpha = \mathbb{E}[X \mid X \geq q_\alpha(X)]$.

Analogous to the return-based Value-at-Risk (VaR), we define, for confidence level $\alpha \in [0,1]$, the *maximum drawdown threshold* DT_α to be a quantile of the maximum drawdown distribution:

$$\mathrm{DT}_\alpha\left(\boldsymbol{\mu}(X_{T_n})\right) = \inf\left\{\mu \mid \mathbb{P}\left(\boldsymbol{\mu}(X_{T_n}) > \mu\right) \leq 1-\alpha\right\}$$

It is thus the smallest maximum drawdown μ for which the probability that the maximum drawdown $\boldsymbol{\mu}(X_{T_n})$ exceeds μ is at most $(1-\alpha)$. For example, the 95% maximum drawdown is both a worst case for drawdown in an ordinary period and a best case among extreme scenarios. It separates the 5% worst maximum drawdowns from the rest.

Definition 2.3 (Conditional Expected Drawdown). *At confidence level* $\alpha \in [0,1]$*, the* Conditional Expected Drawdown CED_α *is the function mapping the random variable* $\boldsymbol{\mu}(X_{T_n})$*, representing maximum drawdown within the path* X_{T_n}*, to the expected maximum drawdown given*

that the maximum drawdown threshold at α is breached. More formally,

$$\mathrm{CED}_\alpha\left(X_{T_n}\right) = \mathrm{TM}_\alpha\left(\boldsymbol{\mu}(X_{T_n})\right) = \frac{1}{1-\alpha}\int_\alpha^1 \mathrm{DT}_u\left(\boldsymbol{\mu}(\mathrm{X_{T_n}})\right)\mathrm{d}u.$$

If the distribution of $\boldsymbol{\mu}(X_{T_n})$ is continuous, then CED_α is equivalent to the tail conditional expectation:

$$\mathrm{CED}_\alpha\left(\mathrm{X_{T_n}}\right) = \mathrm{TM}_\alpha\left(\boldsymbol{\mu}(\mathrm{X_{T_n}})\right) = \mathbb{E}\left(\boldsymbol{\mu}(\mathrm{X_{T_n}}) \mid \boldsymbol{\mu}(\mathrm{X_{T_n}}) > \mathrm{DT}_\alpha\left(\boldsymbol{\mu}(\mathrm{X_{T_n}})\right)\right).$$

3. Axiomatizing Drawdown Risk

In this Section, we derive theoretical properties of CED, most notably convexity and positive homogeneity.

3.1. **CED as a Path-Dependent Measure of Risk.**

In classical single-period risk assessment, uncertain portfolio outcomes over a fixed time horizon are represented as random variables on a probability space. A risk measure maps each random variable to a real number summarizing the overall position in risky assets of a portfolio.

Definition 3.1 (Risk Measure)**.** *For the probability space $(\Omega, \mathcal{F}, P)$, let $L^0(\Omega, \mathcal{F}, P)$ be the set of all random variables on $(\Omega, \mathcal{F})$. A* risk measure *is a real-valued function $\rho\colon \mathcal{M} \to \mathbb{R}$, where $\mathcal{M} \subset L^0(\Omega, \mathcal{F}, P)$.*[6]

Examples of single-period risk measures are volatility, Value-at-Risk (VaR), and Expected Shortfall (ES). Unlike these return-based risk metrics, however, Conditional Expected Drawdown is defined over random vectors representing return paths rather than one-period portfolio returns or losses. We next formalize this space of return paths, on top of which path-dependent risk measures are defined, as real-valued functionals.

Fix a time horizon t, and define $\mathcal{V}_t \subset L^0(\Omega, \mathcal{F}, P)$ to be the space of random variables $X_t : \Omega \to \mathbb{R}$ representing the return at time t, and note that $\mathcal{V}_t$ is a convex cone. For a path of length $n \in \mathbb{N}$, we can construct the direct sum (or equivalently the coproduct $\coprod$) $\mathcal{V}_{T_n} = \bigoplus_{i=1}^n \mathcal{V}_{t_i}$ using the finite ordered indexing set $T_n = \{t_1, \ldots, t_n\} \subset T$. Then $\mathcal{V}_{T_n}$ is also a convex cone, and it is composed of random vectors $X_{T_n} = (X_{t_1}, \ldots, X_{t_n})$ representing return paths, where $X_{t_i} \in \mathcal{V}_{t_i}$.

Definition 3.2 (Path-dependent risk measure)**.** *Fix a finite ordered set $T_n = \{t_1, \ldots, t_n\} \subset T$. A* path-dependent risk measure *is a real-valued function $\rho_{T_n} : \mathcal{V}_{T_n} \to \mathbb{R}$.*

[6]An axiomatic approach to risk measures was initiated by Artzner et al. (1999). They specified a number of properties that a good risk measure should have, with particular focus on applications in financial risk management. Their main focus is the class of *monetary* such measures, which can translate into capital requirement, hence making risk directly useful to regulators. Since coherent measures of risk were introduced by Artzner et al. (1999), other useful classes of risk measures were proposed, most notably *convex* measures (Föllmer and Schied (2002, 2010, 2011)) and *deviation* measures (Rockafellar et al. (2002, 2006)). We briefly discuss the latter in Section 3.5 and show that CED is a deviation measure.

The two main properties that concern us in this paper are convexity and positive homogeneity. A path-dependent risk measure ρ_{T_n} is *convex* if for all $X_{T_n}, Y_{T_n} \in \mathcal{V}_{T_n}$ and $\lambda \in [0,1]$,

$$\rho_{T_n}\left(\lambda X_{T_n} + (1-\lambda)Y_{T_n}\right) \leq \lambda\rho_{T_n}(X_{T_n}) + (1-\lambda)\rho_{T_n}(Y_{T_n}) \ .$$

The path-dependent risk measure ρ_{T_n} is *positive homogenous* of degree one if for all $X_{T_n} \in \mathcal{V}_{T_n}$ and $\lambda > 0$,

$$\rho_{T_n}(\lambda X_{T_n}) = \lambda\rho_{T_n}(X_{T_n}) \ .$$

By definition, Conditional Expected Drawdown is a path-dependent risk measure mapping $X_{T_n} \in \mathcal{V}_{T_n}$ to $\mathbb{E}\left(\boldsymbol{\mu}(X_{T_n}) \mid \boldsymbol{\mu}(X_{T_n}) > \mathrm{DT}_\alpha\left(\boldsymbol{\mu}(X_{T_n})\right)\right) \in \mathbb{R}$. Since this is the tail-mean $\mathrm{TM}_\alpha\left(\boldsymbol{\mu}(X_{T_n})\right)$ of the maximum drawdown distribution $\boldsymbol{\mu}(X_{T_n})$, we can rewrite CED as the composite of the tail-mean functional TM_α and the function $\boldsymbol{\mu}$ mapping return paths to maximum drawdowns. The domain of the former function and range of the latter function is the space $\mathcal{D}_{T_n} \subset L^0(\Omega, \mathcal{F}, P)$, whose random variables represent maximum drawdowns within return paths at $T_n = \{t_1, \ldots, t_n\}$. Then

$$\mathrm{CED}_\alpha = \mathrm{TM}_\alpha \circ \boldsymbol{\mu},$$

where $\boldsymbol{\mu} : \mathcal{V}_{T_n} \to \mathcal{D}_{T_n}$ maps the random vector X_{T_n} to $\max_{1\leq i<n} \max_{i<j\leq n} \{X_j - X_i, 0\}$, as defined in Section 2.1.

We know that the tail mean is a convex and degree-one positive homogenous measure of risk, independent of the underlying distribution (see Acerbi and Tasche (2002a,b)). To investigate properties of CED with respect to the return universe $\mathcal{V}_{T_n}$, we will need to characterize the transformation $\boldsymbol{\mu}$.

Before proving convexity and positive homogeneity, we first show that CED is not a risk measure in the monetary sense of Artzner et al. (1999), since it is neither translation invariant nor monotonic:

Lemma 3.3. *For all $X_{T_n} \in \mathcal{V}_{T_n}$ and all constant almost surely $C \in \mathcal{V}$, $\mathrm{CED}_\alpha(X_{T_n} + C) = \mathrm{CED}_\alpha(X_{T_n})$ (for all $\alpha \in (0,1)$).*

Proof. The drawdown functional d is invariant under constant deterministic shifts because $d_j(X_{T_n} + C) = \max_{1\leq i\leq j}\{X_{t_i} + C\} - X_{t_j} - C = \max_{1\leq i\leq j}\{X_{t_i}\} - X_{t_j} = d_j(X_{T_n})$. And so $\mathrm{CED}_\alpha(X_{T_n} + C) = \mathrm{CED}_\alpha(\max(d(X_{T_n} + C))) = \mathrm{CED}_\alpha(\max(d(X_{T_n}))) = \mathrm{CED}_\alpha(X_{T_n})$. □

Lemma 3.3 essentially states that by (deterministically) shifting the path of the portfolio value up or down, the drawdown within that path remains the same. Non-monotonicity is similarly easy to derive.

Lemma 3.4. *It is not generally the case that for $X_{T_n}, Y_{T_n} \in \mathcal{V}_{T_n}$ such that $X_{t_i} \leq Y_{t_i}$ (for all $i \leq n$), $\mathrm{CED}_\alpha(X_{T_n}) \geq \mathrm{CED}_\alpha(Y_{T_n})$.*

Proof. For a fixed $j \leq n$, $\max_{1\leq i\leq j}\{X_i\} \leq \max_{1\leq i\leq j}\{Y_i\}$, and therefore $d_j(X_{T_n}) \not\geq d_j(Y_{T_n})$, where $d = (d_1, \ldots, d_n)$ is the drawdown transformation. □

Both translation invariance and monotonicity were originally introduced as desirable properties for risk measures under the assumption that the risk of a position represents the amount of capital that should be added to the position so that it becomes acceptable to the regulator. From a regulatory viewpoint, translation invariance means that adding the value of any guaranteed (that is, deterministic) position to an existing portfolio portfolio simply decreases the capital required by that amount, and vice versa. Moreover, monotonicity essentially states that positions that in any single state of the world lead to higher losses should require more risk capital. We have developed the drawdown risk measure CED not with the regulatory reporting framework in mind, but with the purpose of mathematically formalizing drawdown in a way that is amenable to risk analysis and management. This is of particular interest to the asset management community.

We proceed to derive two theoretically and practically important properties of CED, namely convexity and positive homogeneity.

3.2. **Convexity of CED.** According to Föllmer and Schied (2002, 2010, 2011), the essence of diversification is encapsulated in the convexity axiom. Suppose we have two random variables P_1 and P_2 representing returns to two portfolios. Rather than investing fully in one of the two portfolios, an investor could *diversify* by allocating a fraction $\lambda \in [0,1]$ of his capital to, say, P_1, and the remainder $1-\lambda$ to P_2. Under a convex risk measure, this diversification cannot increase risk.

Lemma 3.5. *The maximum drawdown transformation $\boldsymbol{\mu} : \mathcal{V}_{T_n} \to \mathcal{D}_{T_n}$ is convex.*

Proof. Recall that we can define maximum drawdown as the maximum within a path of drawdowns, that is by $\boldsymbol{\mu}(X_{T_n}) = \max(d(X_{T_n})) = \max_{1\le i\le n}\{d_{t_i}\}$. We show that each real-valued component $d_j : \mathbb{R}^n \to \mathbb{R}$ of the vector-valued transformation $d : \mathbb{R}^n \to \mathbb{R}^n$ given by $d(X_{T_n}) = (d_1(X_{T_n}), \ldots, d_n(X_{T_n}))$ is convex. For the j-th real-valued component d_j, we have for $\lambda \in [0,1]$ and paths $X_{T_n} = (X_{t_1}, \ldots, X_{t_n})$ and $Y_{T_n} = (Y_{t_1}, \ldots, Y_{t_n})$

$$\begin{aligned} d_j(\lambda X_{T_n} + (1-\lambda)Y_{T_n}) &= \max_{1\le i\le j}\{\lambda X_{t_i} + (1-\lambda)Y_{t_i}\} - \left(\lambda X_{t_j} + (1-\lambda)Y_{t_j}\right) \\ &\le \lambda \max_{1\le i\le j}\{X_{t_i}\} + (1-\lambda)\max_{1\le i\le j}\{Y_{t_i}\} - \lambda X_{t_j} - (1-\lambda)Y_{t_j} \\ &= \lambda\left(\max_{1\le i\le j}\{X_{t_i}\} - X_{t_j}\right) + (1-\lambda)\left(\max_{1\le i\le j}\{Y_{t_i}\} - Y_{t_j}\right) \\ &= \lambda d_j(X_{T_n}) + (1-\lambda)d_j(Y_{T_n}) \end{aligned}$$

Finally, $\boldsymbol{\mu}$ is convex, since the maximum of a set of convex functions is a convex function. □

Because the tail-mean functional is also convex and monotonically non-decreasing, its composite with $\boldsymbol{\mu}$ is also convex, and so we immediately obtain the following:

Proposition 3.6 (Convexity of CED)**.** *The path-dependent risk measure $\mathrm{CED}_\alpha : \mathcal{V}_{T_n} \to \mathbb{R}$ is convex with respect to portfolio weights.*

3.3. **Positive Homogeneity of CED.** Degree-one positive homogenous risk measures are characterized by Euler's homogenous function theorem, and hence play a prominent role in portfolio risk analysis. More precisely, for a portfolio return $P = \sum_i w_i X_i$ in $\mathcal{M}$, we know that a risk measure $\rho : \mathcal{M} \to \mathbb{R}$ is postive homogenous of degree one if and only if $\sum_i w_i \left(\partial \rho(P)\right) / (\partial w_i) = \rho(P)$.[7] The risk $\rho(P)$ of the portfolio $P = \sum_i w_i X_i$ can therefore be linearly attributed along its factors X_i.

The tail-mean functional is positive homogenous. To see that the drawdown transformation $\boldsymbol{\mu} : \mathcal{V}_{T_n} \to \mathcal{D}_{T_n}$ is also positive homogenous, note that the components $d_j(X_{T_n}) = \max_{1 \le i \le j}\{X_{t_i}\} - X_{t_j}$ of the drawdown transformation $d = (d_1, \ldots, d_n)$ are invariant under multiplication, since $\lambda d_j(X_{T_n}) = \lambda \left(\max_{1 \le i \le j}\{X_{t_i}\} - X_{t_j}\right) = \max_{1 \le i \le j}\{\lambda X_{t_i}\} - \lambda X_{t_j} = d_j(\lambda X_{T_n})$. Since positive homogeneity is preserved under composition, we have the following:

Proposition 3.7 (Positive homogeneity of CED)**.** *The path-dependent risk measure* $\mathrm{CED}_\alpha : \mathcal{V}_{T_n} \to \mathbb{R}$ *is positive homogenous with respect to portfolio weights.*

3.4. **CED as a Deviation Measure.** We show that Conditional Expected Drawdown is a *generalized deviation measure*, as developed by Rockafellar et al. (2002, 2006). Broadly speaking, deviation measures obey axioms taken from the properties of measures such as standard deviation and semideviation. We generalize these axioms to our path-dependent universe.

Definition 3.8 (Generalized Path-Dependent Deviation Measure)**.** *A generalized path-dependent* deviation measure *is a path-dependent risk measure* $\delta : \mathcal{V}_{T_n} \to \mathbb{R}$ *satisfying the following axioms:*

- (D0) *Normalization: for all constant deterministic* $C_{T_n} \in \mathcal{V}_{T_n}$, $\delta(C_{T_n}) = 0$.
- (D1) *Positivity: for all* $X_{T_n} \in \mathcal{V}_{T_n}$, $\delta(X_{T_n}) \ge 0$.
- (D2) *Shift invariance: for all* $X_{T_n} \in \mathcal{V}_{T_n}$ *and all constant deterministic* $C_{T_n} \in \mathcal{V}_{T_n}$, $\delta(X_{T_n} + C_{T_n}) = \delta(X_{T_n})$.
- (D3) *Positive degree-one homogeneity: for all* $X_{T_n} \in \mathcal{V}_{T_n}$ *and* $\lambda > 0$, $\delta(\lambda X_{T_n}) = \lambda \delta(X_{T_n})$.
- (D4) *Convexity: for all* $X_{T_n}, Y_{T_n} \in \mathcal{V}_{T_n}$ *and* $\lambda \in [0, 1]$, $\delta(\lambda X_{T_n} + (1-\lambda) Y_{T_n}) \le \lambda \delta(X_{T_n}) + (1-\lambda)\delta(Y_{T_n})$.

Positive homogeneity and convexity of CED imply that CED satisfies axioms (D3) and (D4). From Lemma 3.3 we know that, for confidence level $\alpha \in (0, 1)$, $\mathrm{CED}_\alpha(X_{T_n} + C_{T_n}) = \mathrm{CED}_\alpha(X_{T_n})$, hence CED satisfies axiom (D2). Note also that any portfolio of zero value and, more generally, of constant deterministic value is not exposed to drawdown risk, and so for all constant deterministic $C_{T_n} \in \mathcal{V}_{T_n}$, we have $\mathrm{CED}_\alpha(C_{T_n}) = 0$ (axiom (D0)). Finally, CED is always non-negative because the maximum drawdown is by definition non-negative, and so CED satisfies (D1).

Proposition 3.9. *Conditional Expected Drawdown is a generalized path-dependent deviation measure.*

[7] This formula and the topic of risk attribution is discussed in more detail in Section 4.

4. Drawdown Risk Attribution

With the theoretical framework of drawdown risk measurement in place, the next step is to understand how Conditional Expected Drawdown can be integrated in the investment process. We show how to systematically analyze the sources of drawdown risk within a portfolio and how these sources interact. In practice, investors may be interested in attributing risk to individual securities, asset classes, sectors, industries, currencies, or style factors of a particular risk model. In what follows, we assume a generic such risk factor model.

Fix an investment period and let F_i denote the return of factor i over this period ($1 \leq i \leq n$). Then the portfolio return over the period is given by the sum

$$P = \sum_{i=1}^{n} w_i F_i \quad ,$$

where w_i is the portfolio exposure to factor i and the summand representing idiosyncratic risk is not included for simplicity. Because portfolio risk is not a weighted sum of source risks, there is no direct analog to this decomposition for risk measures. However, there is a parallel in terms of *marginal risk contributions* (MRC), which are interpreted as a position's percent contribution to overall portfolio risk. They provide a mathematically and economically sound way of decomposing risk into additive subcomponents.

For a risk measure ρ, the marginal contribution to risk of a factor is the approximate change in overall portfolio risk when increasing the factor exposure by a small amount, while keeping all other exposures fixed.[8] Formally, marginal risk contributions can be defined for any differentiable risk measure ρ.

Definition 4.1. *For a factor F_i in the portfolio $P = \sum_i w_i F_i$, its* marginal risk contribution MRC_i *is the derivative of the underlying risk measure ρ along its exposure w_i:*

$$\mathrm{MRC}_i^{\rho}(P) = \frac{\partial \rho(P)}{\partial w_i}.$$

If ρ is homogenous of degree one, the overall portfolio risk can be decomposed using Euler's homogoneous function theorem as follows:

$$\sum_i w_i \mathrm{MRC}_i^{\rho}(P) = \sum_i \mathrm{RC}_i^{\rho}(P) = \rho(P),$$

where $\mathrm{RC}_i^{\rho}(P) = w_i \mathrm{MRC}_i^{\rho}(P)$ is the i-th total risk contribution *to ρ. Finally,* fractional risk contributions

$$\mathrm{FRC}_i^{\rho}(P) = \frac{\mathrm{RC}_i^{\rho}(P)}{\rho(P)}$$

denote the fractional contribution of the i-th factor to portfolio risk.

[8]Risk contributions have become part of the standard toolkit for risk management, and they are used for risk budgeting and capital allocation. We refer the reader to Tasche (2000), Kalkbrener (2005), Denault (2001), and Qian (2006) for more details.

4.1. **Drawdown Risk Contributions.** Menchero and Poduri (2008) and Goldberg et al. (2010) developed a standard toolkit for analyzing portfolio risk using a framework centered around marginal risk contributions. By integrating drawdown risk into this framework, investors can estimate how a trade would impact the overall drawdown risk of the portfolio. Because Conditional Expected Drawdown is positive homogenous, the individual factor contributions to drawdown risk add up to the overall drawdown risk within a path $P_{T_n} = (P_{t_1}, \dots, P_{t_n})$ of returns to a portfolio with values at time t_j $(j \leq n)$ given by $P_{t_j} = \sum_i w_i F_{i,t_j}$ [9]:

$$\mathrm{CED}_\alpha(P_{T_n}) = \sum_i w_i \mathrm{MRC}_i^{\mathrm{CED}_\alpha}(P_{T_n}), \quad \alpha \in [0,1]. \tag{4.1}$$

Recall that a marginal risk contribution is a partial derivative, and so practitioners can implement Formula 4.1 using numerical differentiation. However, this tends to introduce noise. Moreover, in practice simulation engines don't usually have an analytical formula for differentiation. We next show that an individual marginal contribution to drawdown risk can be expressed as an integral, and this reduces noise, since integration is a smoothing operator.[10]

The individual marginal contribution $\mathrm{MRC}_i^{\mathrm{CED}_\alpha}$ of the i-th factor to overall portfolio drawdown risk $\mathrm{CED}_\alpha(P_{T_n})$ is given by the expected drop of the i-th factor in the interval $[t_{j*}, t_{k*}]$ where the overall portfolio maximum drawdown $\boldsymbol{\mu}(P_{T_n})$ occurs, given that the maximum drawdown of the overall portfolio exceeds the drawdown threshold. This definition is analogous to the marginal contribution to shortfall, and we formalize it next.

Proposition 4.2. *Marginal contributions to drawdown risk are given by:*

$$\mathrm{MRC}_i^{\mathrm{CED}_\alpha}(P_{T_n}) = \mathbb{E}\left[\left(F_{i,t_{k*}} - F_{i,t_{j*}}\right) \mid \boldsymbol{\mu}(P_{T_n}) > \mathrm{DT}_\alpha(P_{T_n})\right], \tag{4.2}$$

where $\mathrm{CED}_\alpha(P_{T_n})$ *is the overall portfolio CED,* $\boldsymbol{\mu}(P_{T_n})$ *is the maximum drawown random variable,* $\mathrm{DT}_\alpha(\mathrm{P_{T_n}})$ *is the portfolio maximum drawdown threshold at* α*, and* $j^* < k^* \leq n$ *are such that:*

$$\boldsymbol{\mu}(P_{T_n}) = \max_{1 \leq j < n} \max_{j < k \leq n} \max\left\{P_{t_k} - P_{t_j}, 0\right\} = P_{t_{k*}} - P_{t_{j*}},$$

and we assume that the maximum drawdown of $P_{T_n} = \sum_i w_i F_{i,T_n}$ *is strictly positive.*

Proof. Most of the following is based on Tasche (2002), Goldberg et al. (2010) and McNeil et al. (2005), who show that the i-th marginal contribution to Expected Shortfall ES_α at confidence level $\alpha \in (0,1)$ of a random variable $P = \sum_i w_i Y_i$ representing portfolio loss is given by

$$\mathrm{MRC}_i^{\mathrm{ES}_\alpha}(P) = \mathbb{E}\left[Y_i \mid P > \mathrm{Var}_\alpha(P)\right], \tag{4.3}$$

where $\mathrm{Var}_\alpha(P)$ denotes the Value-at-Risk of P at α, that is the α-quantile of the loss distribution P.

[9] The path of the i-th factor F_i is written as F_{i,T_n} with the j-th entry within that path given by F_{i,t_j}.

[10] This is analogous to marginal contributions to Expected Shortfall, which can also be expressed as integrals; see Tasche (2000) and Tasche (2002) where it is shown that for quantile based risk measures (such as VaR and ES, but also spectral measures), an Euler attribution can be expressed as an intuitive expectation.

Because the maximum drawdown functional $\boldsymbol{\mu}$ is not additive, Formula 4.3 cannot be immediately applied to a random variable representing maximum drawdown. More precisely, unlike losses, we do not generally have that $\boldsymbol{\mu}(P_{T_n})$ equals $\sum_i w_i \boldsymbol{\mu}(F_{i,T_n})$. But we are able to derive an analog to Formula 4.3 nevertheless.

Assuming that the maximum drawdown of $P_{T_n} = \sum_i w_i F_{i,T_n}$ is strictly positive, let

$$\boldsymbol{\mu}(P_{T_n}) = \max_{1 \le j < n} \max_{j < k \le n} \max \left\{ P_{t_k} - P_{t_j}, 0 \right\} = P_{t_{k*}} - P_{t_{j*}}$$

for some $j^* < k^* \le n$. Then the i-th marginal contribution $\mathrm{MRC}_i^{\mathrm{CED}_\alpha}(P_{T_n})$ to overall portfolio drawdown risk $\mathrm{CED}_\alpha(P_{T_n})$ is given by

$$\begin{aligned}
\mathrm{MRC}_i^{\mathrm{CED}_\alpha}(P_{T_n}) &= \frac{\partial}{\partial w_i} \left(\mathrm{TM}_\alpha \left(\boldsymbol{\mu}(P_{T_n}) \right) \right) \\
&= \frac{\partial}{\partial w_i} \mathbb{E} \left[\boldsymbol{\mu}(P_{T_n}) \mid \boldsymbol{\mu}(P_{T_n}) > \mathrm{DT}_\alpha(P_{T_n}) \right] \\
&= \frac{\partial}{\partial w_i} \mathbb{E} \left[(P_{t_{k*}} - P_{t_{j*}}) \mid \boldsymbol{\mu}(P_{T_n}) > \mathrm{DT}_\alpha(P_{T_n}) \right] \\
&= \frac{\partial}{\partial w_i} \mathbb{E} \left[\left(\sum_{i=1}^n w_i F_{i,t_{k*}} - \sum_{i=1}^n w_i F_{i,t_{j*}} \right) \mid \boldsymbol{\mu}(P_{T_n}) > \mathrm{DT}_\alpha(P_{T_n}) \right] \\
&= \frac{\partial}{\partial w_i} \mathbb{E} \left[\sum_{i=1}^n w_i \left(F_{i,t_{k*}} - F_{i,t_{j*}} \right) \mid \boldsymbol{\mu}(P_{T_n}) > \mathrm{DT}_\alpha(P_{T_n}) \right] \\
&= \frac{\partial}{\partial w_i} \left(\sum_{i=1}^n w_i \mathbb{E} \left[\left(F_{i,t_{k*}} - F_{i,t_{j*}} \right) \mid \boldsymbol{\mu}(P_{T_n}) > \mathrm{DT}_\alpha(P_{T_n}) \right] \right) \qquad (4.4)
\end{aligned}$$

Using the fact that the partial derivative with respect to the quantile DT_α is zero, as discussed by Bertsimas et al. (2004), Formula 4.4 simplifies to:

$$\mathrm{MRC}_i^{\mathrm{CED}_\alpha}(P_{T_n}) = \mathbb{E} \left[\left(F_{i,t_{k*}} - F_{i,t_{j*}} \right) \mid \boldsymbol{\mu}(P_{T_n}) > \mathrm{DT}_\alpha(P_{T_n}) \right].$$

Finally, note that the variables $k*$ and $j*$ are stochastic. This means that in a Monte Carlo simulation, they will take on a different value scenario by scenario. □

5. Drawdown Risk Optimization

A rigorous mathematical theory of risk measurement can go beyond risk analysis purposes. In particular, it can be used for making risk-based asset allocation decisions. Before incorporating a risk measure other than variance — around which much of risk and portfolio management continues to revolve in practice — into the portfolio construction process, one needs to address the issues of feasibility and potential use. Consider minimum variance optimization, the goal of which is to allocate funds to a selection of assets in such a way that portfolio risk is minimized. Recent work has shown the theoretical feasibility (Rockafellar and Uryasev (2000, 2002)) and

practical applicability (Goldberg et al. (2013)) of downside-safe portfolio construction based on Expected Shortfall.

We extend this line of research by showing that one can allocate assets to trade off CED risk against portfolio return. There are two crucial ingredients for carrying out any optimization in practice. Convexity of the objective function to be minimized ensures that the minimum, if it exists, is a global one. In the context of risk measures, convexity ensures that diversification of a portfolio does not increase risk, as formalized by Föllmer and Schied (2002, 2010, 2011). The second ingredient is the feasibility and efficiency of the optimization algorithm.[11] Having established the convexity of Conditional Expected Drawdown, thereby making it amenable to traditional optimization tools, we next show that its minimization for the purpose of active portfolio construction is indeed feasible and can be implemented efficiently via a linear programming algorithm.

We consider a general asset allocation problem with m assets and weights $\mathbf{w} = (w_1, \ldots, w_m)$.[12] We assume that our optimization is based on a given vector of T' maximum drawdown scenarios $\hat{\boldsymbol{\mu}}_i$. For example, these scenarios may be historical time series or simulations based on a parametric distribution. An estimate $\widehat{\mathrm{CED}}$ of the Conditional Expected Drawdown at, say, a 90% threshold is then given by the average of the 10% worst maximum drawdown scenarios. For $\alpha \in [0, 1]$, we have

$$\widehat{\mathrm{CED}}_\alpha = \frac{1}{K} \sum_{i=1}^{K} \hat{\boldsymbol{\mu}}_{(i)}, \tag{5.1}$$

where $K = \lfloor T'(1-\alpha) \rfloor$, and (i) is used to denote the ordered statistic of the sample scenarios. The drawdown minimization can than be written as:

$$\min_{\mathbf{w}} \qquad \frac{1}{K} \sum_{i=1}^{K} \hat{\boldsymbol{\mu}}_{(i)}. \tag{5.2}$$

This is referred to as a *sample drawdown optimization*, as the input depends on the underlying sample of maximum drawdown scenarios. The optimal weight vector $\mathbf{w}$ does not appear explicitly in Formula 5.2, but is implicit in the maximum drawdown $\boldsymbol{\mu}$. Each scenario $\hat{\boldsymbol{\mu}}_i$ depends on both portfolio returns and weights. We can, however, reformulate this optimization into a linear programming (LP) problem, making it computationally feasible.

The following Theorem is based on the seminal work of Rockafellar and Uryasev (2000, 2002) who developed an efficient linear programming algorithm for minimizing the tail mean of a distribution of returns. The optimization of the tail mean of a maximum drawdown

[11] A third crucial ingredient is having a reliable risk model feeding the optimizer with realistic and useful scenarios. This being beyond the scope of the present article, we have focused on the two main theoretical requirements in the present article. We refer the reader to Zabarankin and Uryasev (2014), where the theory of risk estimation and error sensitivity in the context of portfolio optimization is discussed.

[12] This can be reformulated in terms of linear asset exposures to some factors. Also, note that since CED is convex in the return paths, it is also convex in weights.

distribution follows in a fairly straightforward manner, and is similar to that of Chekhlov et al. (2003, 2005).

Theorem 5.1 (LP formulation of CED optimization)**.** *The drawdown optimization problem of Formula (5.1) is equivalent to the following linear programming optimization:*

$$\begin{aligned} \min_{\mathbf{w},t,z,u} \quad & t + \frac{1}{K}\sum_{i=1}^{T'} z_i \\ \text{s.t.} \quad & z_i + t \geq u_{i,j} - \mathbf{w}'\mathbf{r}_{i,j}; \\ & z_i \geq 0; \quad u_{i,0} = 0; \quad u_{i,j} \geq 0; \quad i \leq T'; \quad j \leq N \end{aligned} \tag{5.3}$$

where $i \leq T'$ indexes over the maximum drawdown scenarios (and return paths), $j \leq N$ over the returns within a path of length N, and $\mathbf{r}_{i,j} = \left(r_{i,j}^{(1)}, \ldots, r_{i,j}^{(m)}\right)$ is a vector of returns to m assets.

6. Empirical Analysis of Drawdown Risk

We analyze historical values of Conditional Expected Drawdown based on daily data for two asset classes: US Equity and US Government Bonds. The US Government Bond Index we use[13] includes fixed income securities issued by the US Treasury (excluding inflation-protected bonds) and US government agencies and instrumentalities, as well as corporate or dollar-denominated foreign debt guaranteed by the US government, with maturities greater than 10 years. These include government agencies such as the Federal National Mortgage Association (Fannie Mae) and the Federal Home Loan Mortgage Corporation (Freddie Mac), which are private companies, without an explicit guarantee. In comparison to US *Treasury* Bond Indices, US Government Bond Indices were highly volatile and correlated with US Equities during the financial crisis of 2008. The effect of this will be seen in our empirical analysis.[14] Summary risk statistics for the two asset classes and three fixed-mix portfolios are shown in Table 6.1.

6.1. Time-varying Drawdown Risk Concentrations.

Using the definition of marginal contributions to Conditional Expected Drawdown (derived in Proposition 18), we look at the time varying contributions to CED. Figure 6.1 displays the daily 6-month rolling fractional contributions to drawdown risk $\text{CED}_{0.9}$ (at the 90% threshold of the 6-month maximum drawdown distribution) of the two asset classes (US Equity and US Bonds) in the balanced 60/40 allocation.[15] Between 1982 and 2008, and between 2012 and 2013, the contributions of US Equity to overall drawdown risk fluctuated between 80% and 100%. Note that this period includes two

[13]See Appendix A for details on the data and their source.

[14]We thank Robert Anderson for pointing out the important distinction between US Government Bond and US Treasury Bond Indices.

[15]See Appendix B for details on the risk estimation and portfolio construction methodologies used. Note also that similar effects can be seen in other fixed-mix portfolios, such as the equal-weighted 50/50 portfolio and the 70/30 allocation. In the following empirical analyses, we will be focusing exclusively on the traditional 60/40 allocation.

	Volatility	$ES_{0.9}$	$CED_{0.9}$ (6M-paths)	$CED_{0.9}$ (1Y-paths)	$CED_{0.9}$ (5Y-paths)
US Equity	18.35%	2.19%	47%	51%	57%
US Bonds	5.43%	0.49%	29%	32%	35%
50/50	9.53%	1.30%	31%	32%	35%
60/40	11.12%	1.35%	33%	35%	38%
70/30	12.92%	1.40%	36%	40%	44%

TABLE 6.1. Summary statistics for daily US Equity and US Bond Indices and three fixed-mix portfolios over the period 1 January 1982 to 31 December 2013. Expected Shortfall and Conditional Expected Drawdown are calculated at the 90% confidence level. Three drawdown risk metrics are calculated by considering the maximum drawdown within return paths of different fixed lengths (6 months, 1 year and 5 years).

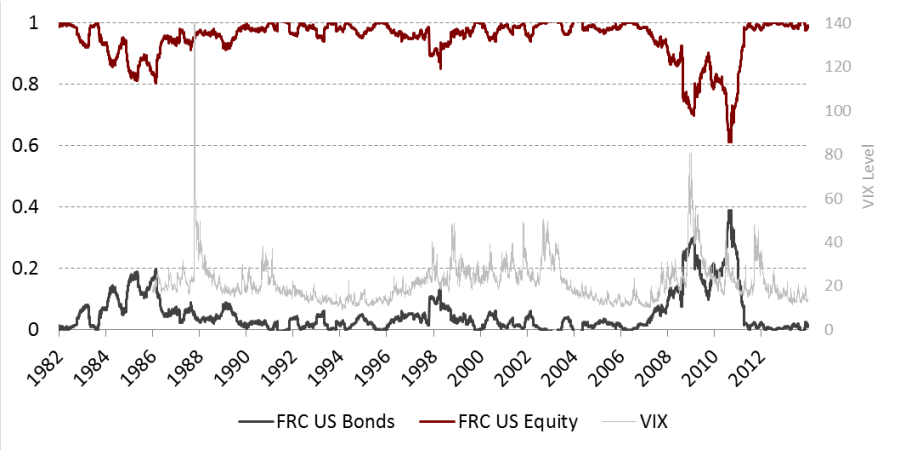


FIGURE 6.1. Daily 6-month rolling Fractional Risk Contributions (FRC) along the 90% Conditional Expected Drawdown (CED) of US Equity and US Bonds to the balanced 60/40 portfolio. Also displayed is the daily VIX series over the period 1982 – 2013, with the right-hand axis indicating its level.

of the three turbulent market regimes that occurred during this 30-year window, namely the 1987 stock market crash and the burst of the internet bubble in the early millennium. During the credit crisis of 2008, however, we see, unexpectedly, that bonds contributed almost as much as equities to portfolio drawdown risk.

Our analysis shows little connection between market turbulence and drawdown risk concentration in the 60/40 fixed mix of US Equity and US Bonds. Notably, the most equitable attribution of drawdown risk occurred during the 2008 financial crisis. This can be explained by the inclusion of bonds issued by Fannie Mae and Freddie Mac in the US Government Bond Index. In calm regimes, these Agency Bonds tended to be correlated with US Treasury bonds,

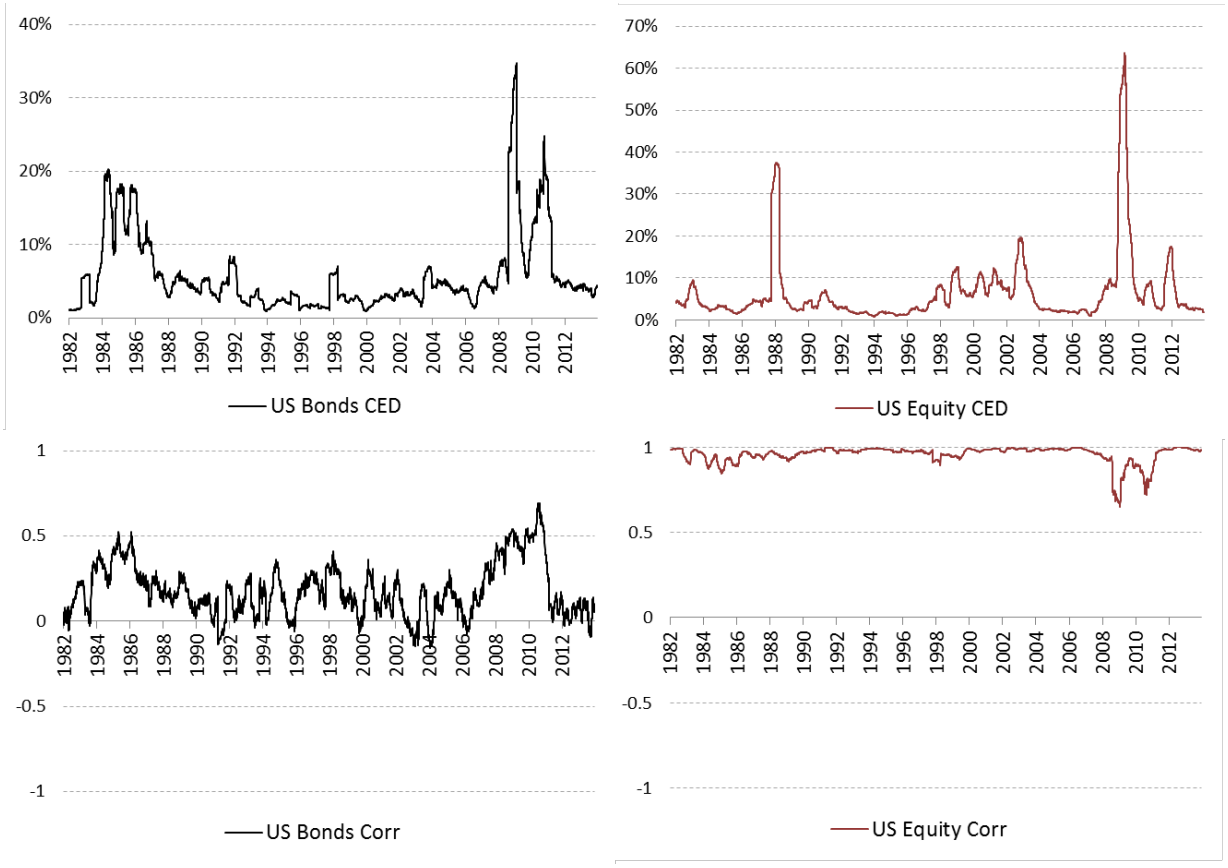

FIGURE 6.2. Decomposition of the individual contributions to drawdown risk $\mathrm{RC}_i^{\mathrm{CED}}(P) = w_i \mathrm{CED}(X_i)\mathrm{Corr}_{\mathrm{i}}^{\mathrm{CED}}$ for the 60/40 allocation to US Equity and US Bonds over the period 1982 – 2013. The top two panels show the daily 6-month rolling standalone 90% Conditional Expected Drawdown (CED) of the two asset classes, while the bottom two panels show the daily 6-month rolling generalized correlations of the individual assets along CED.

but during the financial crisis, Agency Bonds were more correlated with US Equity. For comparison, we provide the same analysis when the underlying Bond Index used is the US Treasury Bond Index (see Figures B.1 and B.2 in Appendix B). In this case, as one would expect, the least equitable attribution of drawdown risk occurred during turbulent market periods.

To understand the sources of the risk contributions, particularly during the credit crisis of 2008 where the concentrations of US Equity and US Government Bonds approached parity, we carry out the "X-Sigma-Rho" decomposition of Menchero and Poduri (2008). Recall from Section 4.1 that risk contribution is proportional to the product of standalone risk and generalized correlation. In the case of Conditional Expected Drawdown, this means that:

$$\mathrm{RC}_i^{\mathrm{CED}}(P) = w_i \mathrm{CED}(X_i)\mathrm{Corr}_{\mathrm{i}}^{\mathrm{CED}}.$$

Because we are working with a fixed-mix portfolio, the exposures w_i are constant: 0.6 and 0.4 for US Equity and US Bonds, respectively. This means that the time-varying risk contributions

of Figure 6.1 depend on the time-varying drawdowns ($\mathrm{CED}(X_i)$) and correlations ($\mathrm{Corr}_i^{\mathrm{CED}}$). Figure 6.2 displays these for each of the two assets in our 60/40 portfolio. Observe that during the 2008 financial crisis, both the drawdown risk contribution of US Bonds and its generalized correlation were elevated relative to the subsequent period. On the other hand, the generalized correlation of US Equity during the 2008 crisis decreased. The combination of these effects may have driven the changes in the drawdown contributions of US Bonds and US Equity during the 2008 crisis.[16]

In Section 6.2, we give a statistical analysis that supports the economic explanation of the increased CED values for US Government Bonds. In practice, investors can efficiently control such regime-dependent fluctuations in drawdown risk concentrations since Conditional Expected Drawdown is a convex risk measure; that is both the return path and the drawdown path are convex functions of asset weights. Hence, they are convex functions of factors that are linear combinations of asset weights. This implies that reducing the portfolio exposure to an asset or factor in a linear factor model decreases its marginal contribution to overall portfolio drawdown.

It is possible for a portfolio to have equal risk contributions with respect to one measure while harboring a substantial concentration with respect to another.[17] Figure 6.3 illustrates such a case. Four portfolios are constructed to be maximally diversified along the following risk measures: volatility, Expected Shortfall, and Conditional Expected Drawdown. The underlying asset classes are US Equity and US Government Bonds as before from 1982 to 2013.[18] We refer to these as being in *parity* with respect to the underlying risk measure. The confidence level for both ES and CED is fixed at 90%. Figure 6.3 shows fractional risk contribution of the equity component to each of three risk measures in three types of risk parity portfolios. Concentrations in terms of drawdown risk, in particular, are revealed. For instance, even though the ES Parity portfolio, which has equal contributions to Expected Shortfall, is constructed to minimize downside risk concentrations, it turns out to have 75% of its drawdown risk concentrated in US Equity.

6.2. **Drawdown Risk and Serial Correlation.** One advantage of looking at maximum drawdown distributions rather than return distributions, and thus Conditional Expected Drawdown rather than Expected Shortfall, lies in the fact that drawdown is inherently path dependent. In other words, drawdown measures the degree to which losses are sustained, as small but persistent cumulative losses may still lead to large drops in portfolio net asset value, and hence may force liquidation. On the other hand, volatility and Expected Shortfall fail to distinguish between intermittent and consecutive losses. We show that, to a greater degree than these two

[16]For comparison, we include in Figure C.1 of Appendix C the risk decomposition along Expected Shortfall.

[17]Risk parity portfolios, which are constructed to equalize risk contributions, have been popular investment vehicles in the wake of the 2008 financial crisis (see Anderson et al. (2012) and Anderson et al. (2014)). This is in spite of the fact that there may be no theoretical basis for the construction.

[18]See Appendix B for details on the data, risk estimation, and portfolio construction methodologies used.

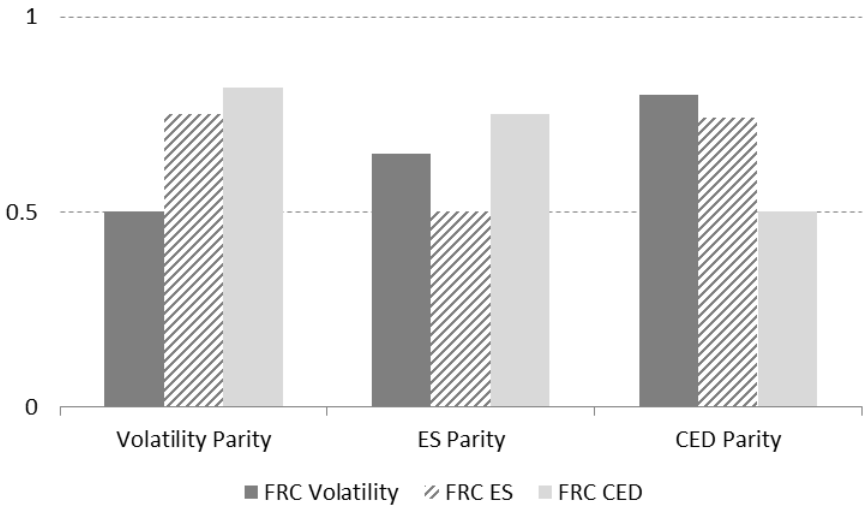

FIGURE 6.3. Fractional Risk Contributions (FRC) of US Equity measured along three different risk measures (volatility, 90% Expected Shortfall and 90% Conditional Expected Drawdown) for the following two-asset portfolios consisting of US Equity and US Bonds over the period 1982–2013: Volatility Parity, ES Parity and CED Parity. Each parity portfolio is constructed to have equal risk contributions along its eponymous risk measure.

risk measures, Conditional Expected Drawdown captures temporal dependence. Moreover, the effect of serial correlation on drawdown risk can be seen in the drawdown risk contributions.

An increase in serial correlation increases drawdown risk. To see how temporal dependence affects risk measures, we use Monte Carlo simulation to generate an autoregressive AR(1) model:

$$r_t = \kappa r_{t-1} + \epsilon_t,$$

with varying values for the autoregressive parameter κ (while ϵ is Gaussian with variance 0.01), and calculate volatility, Expected Shortfall, and Conditional Expected Drawdown of each simulated autoregressive time series. Figure 6.4 displays the results. All three risk measures were affected by the increase in the value of the autoregressive parameter, but the increase is steepest by far for CED. We next use maximum likelihood to fit the AR(1) model to the daily time series of US Equity and US Government Bonds on a 6-month rolling basis to obtain time series of estimated κ values for each asset. The correlations of the time series of κ with the time series of 6-month rolling volatility, Expected Shortfall, and Conditional Expected Drawdown are shown in Table 6.2. The correlations are substantially higher for US Equity across all three risk measures. Note that for both asset classes, the correlation with the autoregressive parameter is highest for CED. Figure 6.5 contains the scatter plots of estimated κ parameters for US Equity and US Bonds against their CED.

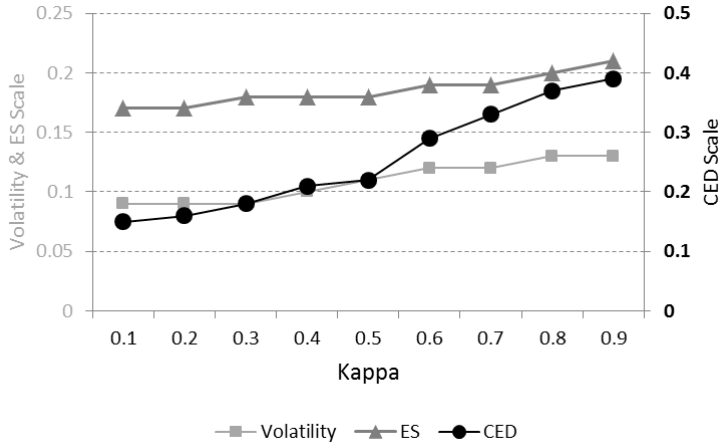

FIGURE 6.4. Volatility, 90% Expected Shortfall (ES), and 90% Conditional Expected Drawdown (CED) of a Monte Carlo simulated AR(1) model (with 10,000 data points) for varying values of the autoregressive parameter κ.

	Volatility	$\text{ES}_{0.9}$	$\text{CED}_{0.9}$
US Equity	0.47	0.52	0.75
US Bonds	0.32	0.39	0.69

TABLE 6.2. For the daily time series of each of US Equity and US Government Bonds, correlations of estimates of the autoregressive parameter κ in an AR(1) model with the values of the three risk measures (volatility, 90% Expected Shortfall and 90% Conditional Expected Drawdown) estimated over the entire period (1982–2013).

An increase in serial correlation increases drawdown risk concentrations. We now show how temporal dependence is manifest in the drawdown risk contributions. Figure 6.6a shows the fractional risk contributions over the entire period 1982–2013 of US Equity to the balanced 60/40 portfolio for three risk measures, volatility, ES, and CED, based on daily data. The fractional contributions of US Equity to volatility and ES were large (over 90%) and close in magnitude. For CED, however, the concentration was less pronounced, which means that the contribution of US Bonds to drawdown risk exceeded its contribution to volatility and shortfall risk. A candidate explanation is temporal dependence: while bonds systematically have lower volatility and shortfall risk than do equities, they do occasionally suffer from extended periods of consecutive losses.

To test this hypothesis, we simulate the returns r_E and r_B to two assets E and B representing equities and bonds, respectively, with an autoregressive AR(1) model:

$$r_{E,t} = \kappa_E r_{E,t-1} + \epsilon_{E,t},$$

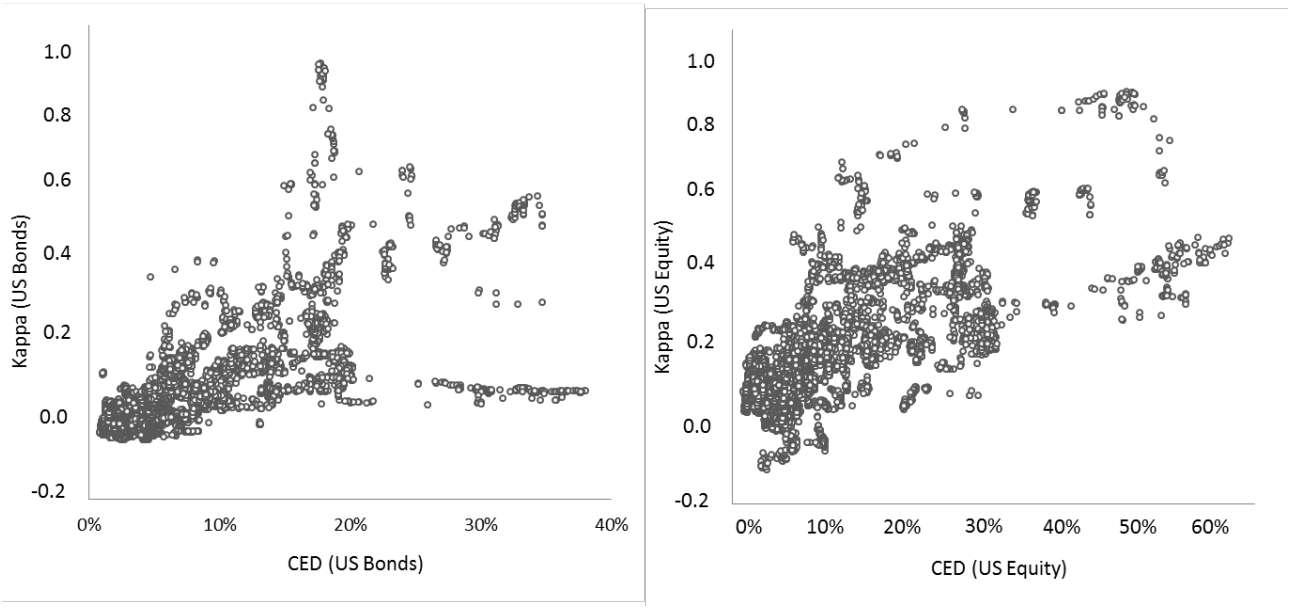

FIGURE 6.5. For each of US Equity and US Government Bonds, scatter plots of the daily time series of 6-month rolling estimates of the autoregressive parameter κ with the 6-month rolling estimates of 90% Conditional Expected Drawdown.

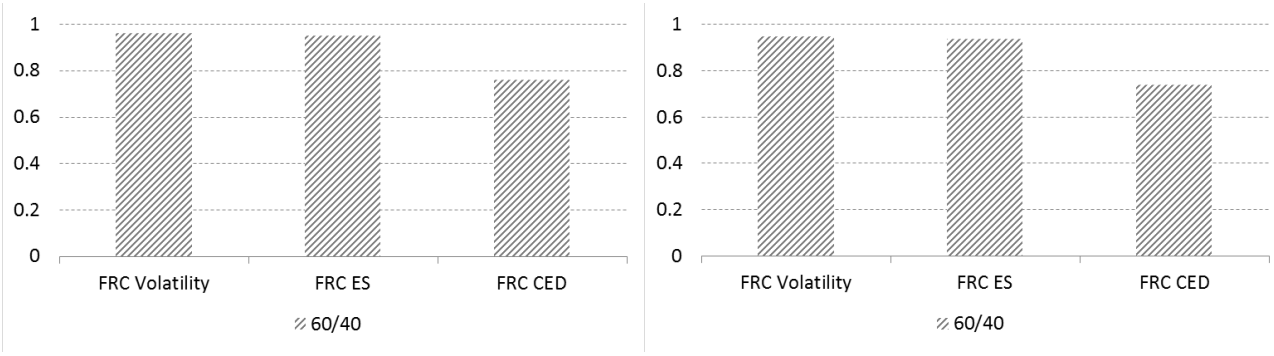
and

$$r_{B,t} = \kappa_B r_{B,t-1} + \epsilon_{B,t},$$

and we construct a simulated 60/40 fixed-mix portfolio. The AR(1) model parameters are obtained by calibrating to daily time series of US Equity and US Bonds. The estimated autoregressive parameters are $\kappa_E = 0.43$ and $\kappa_B = 0.35$. We assume the ϵ variable is Gaussian, with volatility of 18.4% for asset E (based on the volatility of US Equity) and 5.5% for asset B, (based on the volatility of US Bonds). From the simulated data, we fit AR(1) models and their fractional contributions to volatility, ES and CED. When using only the residuals, we obtain statistically equal risk contributions since the innovations are Gaussian. However, without removing the autoregressive component, contributions to CED once again differ from contributions to volatility and ES. Figure 6.6b displays the corresponding fractional contributions of the more volatile asset class, E, to the three risk measures. Note that the two panels in Figure 6.6 are visually indistinguishable even though one is based on historical data, whereas the other is simulated.

7. Drawdown: From Practice to Theory and Back Again

Financial practitioners rely on maximum drawdown as an indicator of investment risk. However, due to its inherent path dependency, maximum drawdown has tended to fall outside of probabilistic treatments of investment risk, which focus on return and loss distributions at fixed horizons. As a result, maximum drawdown has been excluded from standard portfolio



(A) (B)

FIGURE 6.6. (A) Fractional contributions over the entire period 1982–2013 of the US Equity asset to volatility, 90% Expected Shortfall and 90% Conditional Expected Drawdown in the 60/40 portfolio, based on daily data. (B) Fractional contributions of the simulated high-volatility AR(1) asset to volatility, 90% Expected Shortfall and 90% Conditional Expected Drawdown in the 60/40 portfolio.

analysis toolkits that attribute risk to factors or asset classes, and that use risk forecasts as counterweights to expected return in portfolio construction routines.

In this article, we develop a new probabilistic measure of drawdown risk, Conditional Expected Drawdown (CED), which is the tail-mean of a drawdown distribution at a fixed horizon. Since CED is perfectly analogous to the familiar return-based risk measure, Expected Shortfall (ES), CED is easy for practitioners to interpret and it enjoys desirable theoretical properties of tail-means such as positive degree-one homogeneity and convexity. Thus, the development of a consistent theory for drawdown facilitates an extension of its current practical applications.

The path dependency of Conditional Expected Drawdown makes it more sensitive to serial correlation than Expected Shortfall or volatility. We demonstrate this using a simulated AR(1) model. All else equal, CED increases much more rapidly as a function of the autoregressive parameter κ than do Expected Shortfall or volatility. In an empirical study, we find relatively high correlations between serial correlation and estimated CED (.75 for US Equity, .69 for US Bonds) compared to Expected Shortfall (.52 for US Equity, .39 for US Bonds) and volatility (.47 for US Equity, .32 for US Bonds).

Since it is positive degree-one homogenous, CED (like ES and volatility) can be decomposed into a sum of risk contributions, and the relative sensitivity of CED to serial correlation is manifest in risk concentrations. In an empirical study of a balanced 60/40 portfolio of US Equity and US Bonds over the period 1982–2013, US Equity accounted for roughly 75% of CED, but more than 90% of ES and volatility. A plausible explanation is the relatively high level of serial correlation in US Bonds. We support this hypothesis with another simulation: we replicate the empirically observed concentrations of CED, ES and volatility using a simulated

60/40 balanced portfolio based on AR(1) models calibrate to US Equity and US Bonds over the study period.

Since CED is convex, it can serve as a counterweight to expected return in a quantitative optimization. Exploiting the parallels between Expected Shortfall as a tail-mean of a return distribution and Conditional Expected Drawdown as a tail-mean of a drawdown distribution, we formulate optimization against CED as a linear program using the ideas developed in Rockafellar and Uryasev (2000, 2002).

This article lays the foundation needed to incorporate Conditional Expected Drawdown in the investment process. Further empirical exploration of the properties of CED, research into the incremental information it adds beyond what is in return-based risk measures, and the study of its impact on quantitative portfolio construction, are the next steps.

Appendix A. Data and Estimation Methodologies

A.1. **Data.** The data were obtained from the Global Financial Data database. We took the daily time series for the S&P 500 Index and the USA 10-year Government Bond Total Return Index.

A.2. **Portfolio Construction.** Rather than provide thorough realistic empirical analyses of portfolio risk and return, our goal behind the simulated portfolios is to illustrate this article's theoretical development in relation to drawdown risk. For simplicity, we therefore do not account for transaction costs or market frictions in all hypothetical portfolios constructed throughout this study. Moreover, we assume that all portfolios are fully invested and long only.

Fixed-mix portfolios. In the fixed-mix portfolios, rebalancing to the fixed weights is done on a monthly basis. When comparing to other popular rebalancing schemes (quarterly, bi-annually and yearly), similar results were obtained.

Risk parity portfolios. In risk parity strategies, assets are weighted so their ex post risk contributions are equal. As mentioned in Section 5, parity portfolios are not restricted to volatility only, but can be constructed along other risk measures, such as Expected Shortfall and Conditional Expected Drawdown. Asset weights in the strategies depend on estimates of the underlying risk measures (see Section A.3), which are calculated using a 3-year rolling window of trailing returns. Varying the estimation methodology by changing the length of the rolling window or the weighting scheme applied to the returns within this window did not alter our results substantially. Similar to the fixed-mix portfolios, risk parity portfolios are rebalanced monthly, with other rebelancing schemes yielding similar results.

A.3. **Risk Estimation. Volatility.** Portfolio volatility is calculated as the annualized standard deviation of the daily time series over the entire period under consideration. To obtain the volatility risk contributions for a n-asset portfolio $P = \sum_i w_i X_i$, note that the i-th total contribution RC_i^σ to portfolio volatility

$$\sigma(P) = \sum_i w_i^2 \sigma_i^2 + \sum_i \sum_{j \neq i} w_i w_j \sigma_{i,j}$$

is

$$\mathrm{RC}_i^\sigma = w_i^2 \sigma_i^2 + \sum_{j \neq i} w_i w_j \sigma_{i,j},$$

where σ_i^2 is the variance of X_i and $\sigma_{i,j}$ is the covariance of X_i and X_j. Then, the i-th fractional contribution to volatility is given by

$$\mathrm{FRC}_i^\sigma(P) = \frac{w_i^2 \sigma_i^2 + \sum_{j \neq i} w_i w_j \sigma_{i,j}}{\sigma(P)} \quad .$$

Expected Shortfall. For confidence level $\alpha \in (0, 1)$, an estimate for the Expected Shortfall of a portfolio is calculated by ordering the daily return time series over the whole period according to the magnitude of the returns, then averaging over the worst $(1 - \alpha)$ percent

outcomes, more specifically:

$$\widehat{\mathrm{ES}}_\alpha = \frac{1}{K}\sum_{i=1}^{K} r_{(i)},$$

where T is the length of the daily time series, $K = \lfloor T(1-\alpha)\rfloor$, and $r_{(i)}$ is the i-th return of the *magnitude-ordered* time series. To obtain the contributions to shortfall risk, recall that under a continuity assumption, the Expected Shortfall of an asset $X \in \mathcal{M}$ can be expressed as $\mathrm{ES}_\alpha(X) = \mathbb{E}\left(X \mid X \geq \mathrm{VaR}_\alpha(X)\right)$, or the expected loss in the event that its Value-at-Risk at α is exceeded.[19] As usual, let $P = \sum_i w_i X_i$ be the portfolio in consideration. Assuming differentiability of the risk measure VaR, the marginal contribution of X_i to portfolio shortfall $\mathrm{ES}_\alpha(P)$ is given by

$$\mathrm{MRC}_i^{\mathrm{ES}_\alpha}(P) = \frac{\partial \mathrm{ES}_\alpha(P)}{\partial w_i} = \mathbb{E}(X_i \mid P \geq \mathrm{VaR}_\alpha(P)) \quad .$$

An estimate for the i-th marginal contribution to shortfall risk is then obtained by averaging over all the returns of asset X_i that coincide with portfolio returns exceeding the portfolio's Value-at-Risk at threshold α.

Conditional Expected Drawdown. The first step in calculating an estimate for the Conditional Expected Drawdown is to obtain the empirical maximum drawdown distribution. From the historical time series of returns, we generate return paths of fixed length n using a one-day rolling window. This means that consecutive paths overlap. The advantage is that for a return time series of length T, we obtain a maximum drawdown series of length $T - n$, which for large T and small n is fairly large, too. From these $T - n$ return paths we calculate the maximum drawdown as defined in Section 2. An estimate for the Conditional Expected Drawdown at confidence level $\alpha \in (0, 1)$ is then calculated as the average of the largest $(1 - \alpha)$ percent maximum drawdowns. To obtain an estimate for the i-th contribution to drawdown risk CED, we take the average over all the drawdowns of the i-th asset in the path $[t_{j*}, t_{k*}]$ that coincide with the overall portfolio's maximum drawdowns that exceed the portfolio's drawdown threshold DT_α at confidence level α. (Recall that $j^* < k^* \leq n$ are such that $\boldsymbol{\mu}(P_{T_n}) = P_{t_{k*}} - P_{t_{j*}}$.)

[19] See for example McNeil et al. (2005).

Appendix B. Drawdown risk decomposition along a balanced portfolio of US Equity and US Treasury Bonds

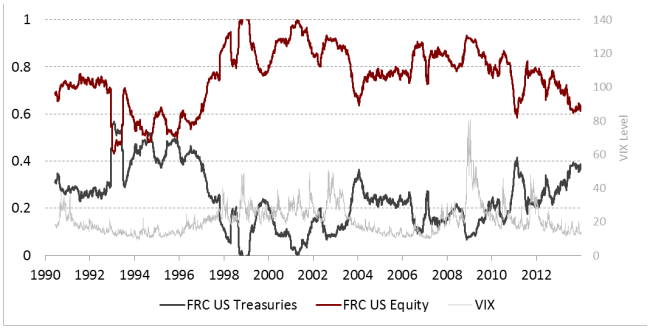


Figure B.1. Daily 6-month rolling Fractional Risk Contributions (FRC) along 90% Conditional Expected Drawdown (CED) of US Equity and US Treasury Bonds to the balanced 60/40 portfolio over the period 1982–2013. Also displayed is the daily VIX series over the same period, with the right-hand axis indicating its level.

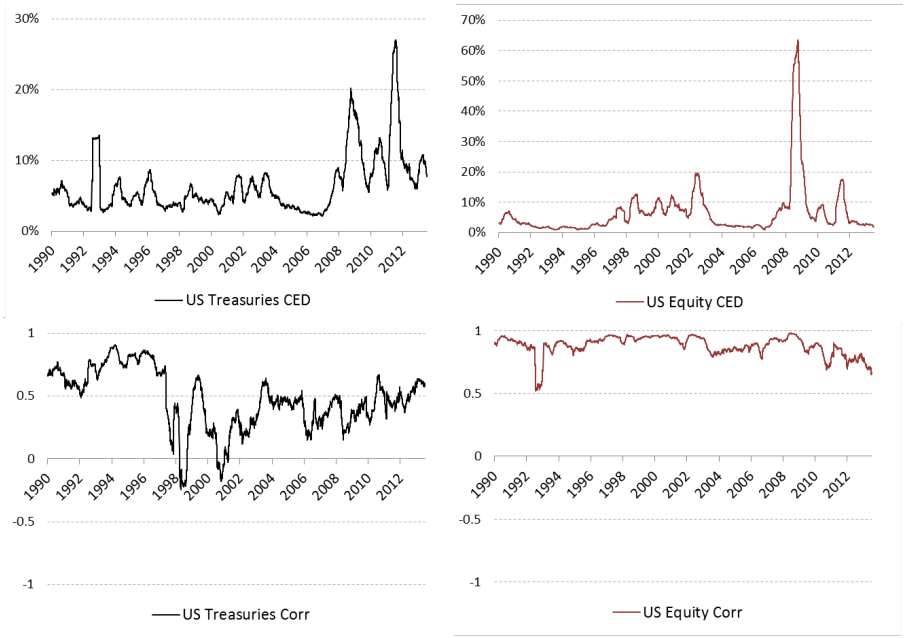

FIGURE B.2. Decomposition of drawdown risk contributions $\mathrm{RC}_i^{\mathrm{CED}}(P) = w_i \mathrm{CED}(X_i)\mathrm{Corr}_{\mathrm{i}}^{\mathrm{CED}}$ for the 60/40 allocation to US Equity and US Treasury Bonds over the period 1982–2013. The top two panels show the daily 6-month rolling standalone 90% Conditional Expected Drawdown (CED) of the two assets, while the bottom two panels show the 6-month rolling generalized correlations of the individual assets along CED.

APPENDIX C. RISK DECOMPOSITION ALONG EXPECTED SHORTFALL
